# 31 Abstract

32 asdf

### 33 Introduction

The mechanisms through which phenotypic diversity emerges and evolves are an essential topic of study in evolutionary biology. Such diversity is the result of a combination of genetic, developmental, and environmental factors that determine the life history of organisms and the evolutionary trajectory of species. These factors might impose certain constraints or offer opportunities for morphological evolution, generating the diversity upon which natural selection acts culminating in the adaptation of species to their surrounding environments. Consequently, the differences in species' ecological preferences (e.g., the exploitation of different habitats) have the potential to drive morphological changes via distinct selective pressures.

41

Ecological specialization is one of the main sources of phenotypic diversity. When organisms colonize new and unique habitats, they are subjected to novel ecological dynamics that may impose different functional requirements. This ecomorphological relationship may result in the repeated evolution of certain phenotypes (i.e., convergence) and the appearance of the so-called ecomorphs, when the general morphological features of the species within a clade can be tightly related to specific ecological contexts. This includes emblematic examples of adaptive radiations such as the differential body size and shape of Anolis species exploiting different microhabitats (Losos 2009), the disparity in beak morphology in Darwin's finches (REFS) and Hawaiian honeycreepers (REFS), or the differences in jaw morphology among cichlid fishes (REFS).

50

However, while the patterns of morphological differences among distinct ecological contexts have been well documented in a variety of vertebrate taxa, the specific trajectories of morphological evolution are in many cases less known. A particularly interesting question is perhaps the extent to which evolutionary allometry can describe this phenotypic differentiation. ALLOMETRY BLABLABLA.

55

The Afro-Arabian geckos in the genus *Pristurus* afford the opportunity to elucidate the interdigitating effects of allometry and habitat specialization on clade-level patterns of phenotypic diversity. Prior work on this system (Tejero-Cicuéndez et al. 2021a) revealed that the colonization of ground habitats has been a trigger of morphological change, specifically reflected in an increase in body size and shape disparity. Interestingly, some ground-dwelling species are among the largest of the genus and also show increased relative head sizes and limb proportions, while some other species with this ecological specialization have evolved to be among the smallest of the group. Additionally, among the species exploiting rocky habitats (the most common ecological feature in *Pristurus*), there are also species with

- both considerably large and small body sizes (Tejero-Cicuéndez et al. 2021a). What remains unexplored,
- 65 however, is how the evolution of body shape is related to differences in body size and whether habitat special-
- 66 ization has an impact in this relationship shape-size. (how this relationship shape-size differs among habitats.)

last paragraph In this study, we used a combination of multivariate morphometric and phylogenetic

69 comparative analysis to interrogate macroevolutionary patterns of evolutionary allometry in *Pristurus* geckos

of Afro-Arabia. Using a combination of phenotypic, phylogenetic, and ecological data, we characterized

allometric trends in body form to discern the extent to which those patterns differed across species occupying

distinct ecological habitats, and to explore how allometric differences related to overall patterns of phenotypic

diversification in the group.

74 The independent diversification of both Socotran and continental taxa, the ecological and behavioural diversity

<sub>75</sub> and the unique phenotypic dataset compiled in this study, make this group of geckos an attractive model

<sub>76</sub> system to investigate keystone dynamics in evolutionary biology such as the island effect and ecological

adaptation, and their impact on morphological evolution.

78 Our findings

Overall our work has ... (some implication).

Our results demonstrate that differing tracectories of allometric growth can result in similar adult phenotypes...

13 (Don't like it! We've got adults, yes?)

#### 82 Materials and Methods

#### 83 Data

We used a combination of phenotypic, phylogenetic, and ecological data to characterize and evaluate intra-

and interspecific allometric trends. The data utilized here were obtained from our prior work on this system

(Tejero-Cicuéndez et al. 2021a, 2022), and are briefly described here. First we used a time-dated, molecular

phylogeny that included all members of the genus *Pristurus*, including several currently undescribed taxa.

The tree was estimated in a Bayesian framework, using five mitochondrial markers, six nuclear markers, and

89 21 calibration points (for details see Tejero-Cicuéndez et al. 2022). Next we categorized each species as

belonging to one of three ecological groups (ground, rock, or tree), based on descriptions of habitat use found

in the literature (see Tejero-Cicuéndez et al. 2021a). Finally, we obtained a phenotypic data set containing

body size (snout-vent length: SVL) and eight linear measurements (Figure 1) that described overall body

form: trunk length (TrL), head length (HL), head width (HW), head height (HH), humerus length (Lhu), ulna length (Lun), femur length (Lfe), and tibia length (Ltb) (Tejero-Cicuéndez et al. 2021a). We restricted our study to those species represented by nine or more individuals; resulting in a dataset of 687 individuals from 25 species (invidivuals per species:  $\mu = 27$ ; min = 9, max = 56). Species in the phenotypic dataset were then matched to the phylogeny, which was subsequently pruned to arrive at the final topology. All measurements were log-transformed prior to statistical analyses. Additional details regarding data collection and formal descriptions of each linear measurement may be found in the original sources (see Tejero-Cicuéndez et al. 2021a, 2022). The data are found on DRYAD: https://doi.org/10.5061/dryad.xwdbrv1f6 (Tejero-Cicuéndez et al. 2021b).

#### Statistical and Comparative Analyses

110

123

We conducted a series of analyses to interrogate allometric trends and macroevolutionary changes in allometry, relative to differentiation in body form. First we characterized evolutionary allometry in the genus by performing a phylogenetic multivariate regression of body form on size, using the species means as data. We then performed an analogous procedure at the individual level, regressing body form on size using our entire dataset. From both the species-level (phylogenetic) and the individual-level regression models, we obtained the set of regression coefficients, and calculated the difference between them to describe the extent to which patterns of allometry at the individual level were concordant with evolutionary allometric trends across species.

Next we used the individual dataset to determine whether allometric trends in body form differed across 111 habitat groups. This was accomplished by performing a multivariate analysis of covariance, with body size 112 (SVL), habitat, and  $SVL \times habitat$  as model effects. Significance was evaluated using 999 iterations of a 113 permutation procedure, where residuals from a reduced model were randomly permuted in each permutation 114 (RRPP), model statistics were recalculated, and used to generate empirical null sampling distributions to 115 evaluate the observed test statistics (following Freedman and Lane 1983; Collyer and Adams 2007; Collyer 116 et al. 2015). We then compared the multivariate allometric vectors for each habitat group by calculating 117 pairwise differences in their angular direction in morphospace, and evaluating these relative to empirical 118 sampling distributions obtained through RRPP (Collyer and Adams 2007; Adams and Collyer 2009; Collyer and Adams 2013). Patterns of multivariate allometry relative to body size were visualized via regression 120 scores (Drake and Klingenberg 2008) and predicted lines (Adams and Nistri 2010), based on the coefficients and fitted values from the linear model described above. 122

We then examined changes in allometric trends across the phylogeny. Here we treated the head dimensions and limb dimensions separately, as allometric trends could potentially differ between these body regions due to differential functional or selective constraints (Kaliontzopoulou et al. 2010). Because both the head and 126 limb data were multivariate, we first performed a partial least squares analysis (Rohlf and Corti 2000) of the head traits versus SVL, and the limb traits versus SVL, to describe the direction of maximal covaration 128 between each body region and size. PLS scores from each analysis were obtained, and species-specific slopes describing the extent of head and limb allometry within each species were extracted from an analysis of covariance modeled as:  $PLS1_{head} \sim SVL * species$  and  $PLS1_{limb} \sim SVL * species$  respectively. The 131 species-specific allometric slopes were then mapped on the phylogeny of Pristurus using a Brownian motion 132 model of evolution, to qualitatively evaluate shifts in allometry across the phylogeny for the group (for a 133 similar approach see Adams and Nistri 2010).

135

Finally, to relate within-species allometric trends with patterns of phenotypic diversification in the group we generated a phylomorphospace, based on the size-standardized species means obtained from a phylogenetic regression (see Tejero-Cicuéndez et al. 2021a). Here, phenotypic similarities among species, relative to their phylogenetic relationships and habitat affiliations, were observed. All analyses were conducted in R 4.2.1 (R Core Team 2022), using RRPP version 1.3.1 (Collyer and Adams 2018; Collyer and Adams 2022), and scripts written by the authors (available at XXX).

## 42 Results

Using phylogenetic regression, we found significant evolutionary allometry in body form across species  $(N_{sp}=25;\,F=217.9;\,Z=5.53;\,P<0.001).$  Likewise, when allometry in body form was examined across individuals, a similar pattern was observed  $(N_{ind}=687;\,F=7910.8;\,Z=9.20;\,P<0.001).$  Further, the vectors of regression coefficients between the two analyses were highly correlated  $(\rho=0.94)$  and were oriented in nearly parallel directions in morphospace  $(\theta=1.49^{\circ})$ . This revealed that the pattern of multivaraite allometry across individuals was concordant with macroevolutionary trends of interspecific allometry among species of *Pristurus* across the phylogeny.

150

Our analyses also exposed significant differences in the allometry of body form among *Pristurus* utilizing
distinct habitats (Table 1). Here, comparisons of multivariate allometric vectors identified that grounddwelling *Pristurus* displayed a distinct allometric trend as compared with *Pristurus* occupying both the

rock and tree habitats (Table 2). Inspection of the regression coefficients for each trait (Supplemental Information) found steeper allometric coefficients for all head and limb traits in ground-dwelling *Pristurus* as compared with rock and tree-dwelling taxa, corroborating this result. These findings implied that larger individuals of ground-dwelling *Pristurus* species displayed proportionately larger heads and limbs, as compared with large individuals in taxa utilizing other habitat types. A visualization of multivariate allometric trends (Fig. 2) confirmed these statistical findings, and indicated that the allometric trajectory in rock-dwelling animals was more extreme as compared with either ground or tree-dwelling *Pristurus*.

161

When allometric patterns were mapped on the phylogeny, traitgrams elucidated that changes in allometric 162 trends were not concentrated to specific regions of the phylogeny (Figure 3). Rather, increases and 163 decreases in allometry of both the head traits and the limb traits occurred repeatedly (see also Supplemental 164 Information). When these patterns were viewed relative to body size, large ground-dwelling species tended to display steeper head allometry as compared to large rock-dwelling species; who displayed shallower head 166 allometry (Figure 3A). Likewise, a similar pattern was observed when comparing small species utilizing these habitats. In contrast, large ground-dwelling species exhibited intermediate patterns of limb allometry, and 168 small species in general were more variable in their patterns of limb allometry (Figure 3B). Inspection of traitgrams thus revealed some degree of discordance in patterns of allometry across body regions; a pattern 170 evidenced by the relatively low correlation between slopes representing head and limb allometry respectively  $(\rho = 0.42).$ 172

173

When body shape differentiation in *Pristurus* was viewed in phylomorphospace (Figure 4), we found broad 174 overlap among habitat groups, though arboreal (tree-dwelling) species were somewhat more separated in 175 morphospace. Rock-dwelling species occupied a slightly larger region of morphospace as compared with the other groups, though this pattern was not statistically significant (Supplemental Information). Intriguingly, 177 when viewed in relation to body size, large *Pristurus* species were not localized to a particular region of morphospace, nor were smaller species. Instead, the largest rock-dwelling species were found in close proximity to the smallest ground-dwelling species, indicating that they were similar in overall body shape. Likewise, the 180 smaller rock-dwelling species were found close to large ground-dwelling species in morphospace, indicating 181 they displayed similar body shapes as well. Finally, integrating the patterns revealed in the phylomorphospace 182 with those identified in our earlier analyses revealed a complex interplay between body shape, body size, and multivariate allometry in *Pristurus*; where species with similar body shapes displayed differing overall size. 184 were found in distinct habitats, and exhibited different allometric trends.

## 186 Discussion

- First paragraph; restate topic/questions (see last par of Intro); summarize general findings ...
- something about linking allometry and phenotypic diversification?
- result 1: implication
- result 2: implication
- result 3: implication
- morphospace: Thus there was a reciprocal relationship between body shape and body size across ground-dwelling and rock-dwelling species.
- one interesting... head vs. (correlation of head vs. limb slopes: 0.42. Pretty low. Implies some sort of differential something here, resulting in distinct allometric patterns for these two body regions.

  SImilar to Antigoni's work (and refs therein). IMPLICATION: tie this into integration/modularity.

  Less integrated across the whole organism, and more modular... Future studies should examine this.
- 198 closing paragraph
